Disclosure Statement

KOM and AMD have nothing to disclose. DTT serves on advisory boards for Sobi, BEAM, and Janssen and receives grant funding from BEAM and NeoImmune Tech. SAG has received research and/or clinical trial support from Novartis, Servier, Vertex, and Kite, and has participated in consulting, study steering committees, or scientific/clinical advisory boards for Novartis, Allogene, CBMG, Cellectis, Adaptimmune, Eureka, TCR2, Juno, GlaxoSmithKline, Vertex/CRISPR, Humanigen, and Roche. SLM reports clinical trial support: Novartis; consulting, advisory boards, or study steering committee: Novartis, Kite, and Wugen.
1-2 Sentence Summary

Here we review the pathophysiology and management of cytokine release syndrome (CRS) secondary to immunotherapy, and potential options for CRS refractory to IL-6 inhibition and glucocorticoids, for which there are no proven treatments. To illustrate, we describe a patient with B-acute lymphoblastic leukemia who developed refractory grade 4 CRS following CD19-directed chimeric antigen receptor T-cell therapy, treated with tocilizumab, methyprednisolone, siltuximab, and the interferon-γ inhibitor emapalumab, with complete remission from leukemia for 12 months.

Introduction

Chimeric antigen receptor (CAR)-modified T cells have emerged as highly effective therapies in the treatment of hematologic malignancies. High rates of remission and durable responses in the treatment of relapsed and refractory pediatric and young adult B-acute lymphoblastic leukemia (B-ALL), diffuse large B-cell lymphoma (DLBCL), primary mediastinal B-cell lymphoma (PMBCL) and mantle cell lymphoma (MCL) have resulted in the Food and Drug Administration (FDA) approval of tisagenlecleucel (Kymriah), axicabtagene ciloleucel (Yescarta), lisocabtagene maraleucel (Breyanzi), and brexucabtagene autoleucel (Tecartus), and there are innumerable CAR T-cell and IEC therapies being studied in clinical and pre-clinical trials. Tisagenlecleucel resulted in complete remission (CR) rates of >80% in children and young adults with relapsed/refractory B-ALL and 40% in adults with relapsed/refractory DLBCL\textsuperscript{1,2}. Axicabtagene ciloleucel and lisocabtagene maraleucel have demonstrated similarly impressive responses in DLBCL\textsuperscript{3,4}. The successes of these transformative immunotherapies are leading to widespread...
use, but are accompanied by the challenge of managing their major acute toxicities: cytokine release syndrome (CRS) and immune effector cell-associated neurotoxicity syndrome (ICANS). CRS is a systemic inflammatory response mediated by immune cell activation and release of high levels of cytokines. Incidence of CRS varies depending on the underlying disease and immunotherapy used, but is reported following CAR T-cell therapies in up to 93% of patients and is grade 3 and above in up to 47% of patients\(^1,3\). The pathophysiology of CRS involves T-cell proliferation promoting macrophage activation and cytokine release, in addition to endothelial dysfunction\(^5,6\). This cascade results in the onset, at a median of 3-7 days post CAR T-cell infusion, of clinical manifestations that range from fever and flu-like symptoms to life-threatening toxicities such as hypotension, vascular leak, coagulopathy, and multi-organ failure\(^3,5,6\). In its severe form, CRS symptomatology shares features of hemophagocytic lymphohistiocytosis (HLH), which appears to be on the spectrum of CRS. Indeed, in pediatric patients with ALL treated with tisagenlecleucel (formerly known as CTL019), we found that all patients with severe CRS met HLH-2004 criteria for HLH\(^5\), and the association of CRS with HLH manifestations was recently reported with a CD22-directed CAR T-cell product\(^8\). Common laboratory abnormalities in severe CRS include hyperferritinemia, elevated c-reactive protein (CRP), transaminitis, and coagulopathy marked by hypofibrinogenemia. Abnormal cytokine levels are seen, including elevations in interleukin-1 (IL-1), IL-6, IL-8, IL-10, interferon-gamma (IFN-γ), tumor necrosis factor-alpha (TNF-α), granulocyte macrophage-colony stimulating factor (GM-CSF), IP10 (CXCL10), MCP1, MIG (CXCL9), and MIP1β, a pattern shared with HLH\(^5-7\). It is notable that both high-grade CRS and HLH manifest substantial elevations in interferon-γ (IFN-γ)\(^5,8\). In HLH, IFN-γ is considered a key driver of inflammation, and interestingly, elevated IFN-γ following CAR T-cell infusion and prior to the onset of CRS has
been shown to predict grade 4 or 5 CRS\textsuperscript{5,8,9}. Additionally, IFN-ɣ is one of the several serum cytokines that are differentially elevated in patients with neurologic toxicity post CAR T-cell therapy\textsuperscript{10}. However, IFN-ɣ blockade has not been explored in the treatment of CRS, with no blocking agent available until recently.

Consensus recommendations for the management of high-grade CRS include the use of supportive care and CRS-directed therapies, such as cytokine blockade using the IL-6 receptor antagonist, tocilizumab, and glucocorticoids\textsuperscript{11}. For CRS refractory to these therapies, no standardized treatment regimen exists, but blockade of alternative cytokine pathways (anakinra, IL-1 receptor antagonist; siltuximab, IL-6 monoclonal antibody; etanercept, TNFα-inhibitor), tyrosine kinase inhibitors (including dasatinib and ruxolitinib), cyclophosphamide, and extracorporeal cytokine adsorption devices have been proposed\textsuperscript{11–14}. In ICANS, glucocorticoids and supportive care are recommended, but tocilizumab has not been shown to be beneficial\textsuperscript{11}.

Emapalumab is a fully human anti-IFN-ɣ monoclonal antibody that was FDA-approved for the treatment of adult and pediatric primary HLH in 2018 after demonstrating significant improvements in parameters of HLH including thrombocytopenia, neutropenia, hypofibrinogenemia, and hyperferritinemia in patients that had recurrent or refractory HLH following standard of care chemotherapy with dexamethasone and etoposide\textsuperscript{9}. In a phase 2/3 study, 10 out of 12 patients with neurological manifestations of HLH showed normalization or improvement in neurologic symptoms of HLH after being treated with emapalumab\textsuperscript{9}. As IFN-ɣ is thought to be a critical cytokine in driving HLH\textsuperscript{9}, and elevated IFN-ɣ is associated with and predictive of severe CRS\textsuperscript{5} and associated with ICANS\textsuperscript{10}, it is intriguing to consider as a target for inhibition in the management of refractory and life-threatening CRS or ICANS\textsuperscript{12}. While theoretical concerns exist that IFN-ɣ blockade could negatively affect T cell cytolytic activity,
pre-clinical data has suggested equivalent cytotoxicity against hematologic malignancies in vitro and in vivo with IFN-γ inhibition or knockout in CAR T cells when compared with IFN-γ-producing CAR T cells\textsuperscript{15}. To our knowledge, the clinical use of emapalumab has not been described in the treatment of CAR T-cell-mediated toxicities. Here, we describe a patient with refractory B-ALL treated with tisagenlecleucel who developed grade 4 CRS refractory to tocilizumab and glucocorticoids, and received siltuximab and emapalumab with subsequent resolution of fevers and hypotension and improvements in hyperferritinemia, CRP, and coagulopathy. Leukemia remission and B-cell aplasia were achieved and sustained for 12 months after tisagenlecleucel infusion, suggesting CD19-directed CAR T-cell persistence.

Case report

A 19-year-old male presented with his first isolated medullary relapse of B-ALL 4 years after his initial diagnosis. After reinduction, bone marrow aspirate and biopsy (BMBA) showed minimal residual disease (MRD) of 9.7%. He then received a 28-day cycle of blinatumomab, after which his MRD increased to 18% with continued CD19 expression. Due to refractory disease, he was referred to our center for CD19-directed CAR T-cell therapy. He underwent leukapheresis and subsequently received bridging chemotherapy with cyclophosphamide, etoposide, and intrathecal methotrexate. He returned to our center for lymphodepleting chemotherapy with cyclophosphamide (500 mg/m\textsuperscript{2} on Days -7 to -6) and fludarabine (30 mg/m\textsuperscript{2} on Days -7 to -4). Prior to tisagenlecleucel infusion, a BMBA demonstrated lymphoblasts accounting for >90% of the cellularity. Outpatient infusion of tisagenlecleucel on day 0 was uncomplicated. On day +2, he was admitted with fever to 38.8°C and tachycardia but was normotensive with normal respiratory exam, classified as grade 1 CRS on the ASTCT grading scale\textsuperscript{11}. Blood cultures were obtained, and he was started on broad spectrum antibiotics. On day+6, he remained febrile and
developed hypotension (grade 2 CRS). He was given 1L of normal saline with minimal
response. A second 1L of normal saline was given with improvement in blood pressure.
Additional fluid resuscitation included transfusion of platelets and packed red blood cells for
ongoing cytopenias. He began showing signs of ICANS with word-finding difficulties and
confusion. While still febrile up to 40.5C, his encephalopathy worsened with agitation.
Hypotension worsened, requiring the initiation of norepinephrine and epinephrine infusions
(grade 4 CRS), and he became hypoxic, requiring supplemental oxygen at 5L/min via nasal
cannula. Eight mg/kg of tocilizumab was given, and his temperature initially improved to 38C
(Figure 1A), but he remained on norepinephrine and epinephrine infusions without the ability to
wean. On day+7, methylprednisolone 60 mg every 12 hours was started. That same day, his
temperature climbed back to 39.7C, and his hypotension worsened prompting the addition of a
vasopressin infusion and increasing vasopressor infusion rates. He was then given
hydrocortisone 100mg and intubated for worsening circulatory failure. A second 8 mg/kg dose of
tocilizumab was given 24 hours after his first dose without a notable change in fever but
vasopressor requirements decreased. On day+8, with ongoing fevers to 40.3C, stalled
vasopressor wean, continued increase in CRP to 21.8 mg/dL, and ferritin to 113,945 ng/mL
(Figure 1B), he was given 11 mg/kg of siltuximab. An echocardiogram was performed
demonstrating mildly diminished cardiac function with left ventricular shortening fraction
(LVSF) of 26%, left ventricular ejection fraction (LVEF) of 57%, and a small pericardial
effusion. He developed profound hypofibrinogenemia and pancytopenia requiring frequent
transfusions with cryoprecipitate, platelets, and red blood cells (Figure 1C-D). A serum cytokine
panel sent on day +8 after 2 doses of tocilizumab and corticosteroids showed elevated IL-6, IL-8,
and IL-10, while IFN-γ was not elevated (Figure 1E). On day+9, high fevers continued, and
vasopressor requirement increased with worsening renal function and profound coagulopathy. An echocardiogram was repeated showing moderately to severely diminished cardiac function with LVSF 24% and LVEF 49%. His ferritin climbed above detectable range at >202,000 ng/mL with a CRP that had downtrended to 8.1 mg/dL, consistent with blockade of IL-6 signaling\textsuperscript{21}. With refractory grade 4 CRS 12 hours after siltuximab and accompanying features of HLH, a decision was made to administer emapalumab on day +9 prior to resulting of the cytokine panel. In concert, a vecuronium infusion was initiated to allow for therapeutic cooling with a cooling blanket, and he received 1 mg/kg of emapalumab. Following these interventions, his temperature normalized and vasopressors rapidly weaned. By day +10, vasopressin and norepinephrine infusions were discontinued, and he remained afebrile. Epinephrine infusion continued to allow diuresis with continuous furosemide infusion. Vecuronium and therapeutic cooling were discontinued. Echocardiogram showed a worsened LVSF of 16% and LVEF (biplane) of 41%, with an elevated brain natriuretic peptide (BNP) of 1012.7 pg/ml. On day+11, worsening renal function (creatinine 5.0 mg/dL), decreased urine output despite initiation of a continuous furosemide infusion, a weight increase of 9%, and an elevated phosphorous of 6.6 mg/dL prompted initiation of continuous venovenous hemodiafiltration (CVVH). On day +12, milrinone infusion was initiated, and bedside echocardiogram noted qualitatively improved function. On day +14, methylprednisolone was stopped after a 3-day wean, he was extubated, and CVVH was discontinued. Following extubation and removal of sedative infusions, his level of alertness improved, but he had ongoing aphasia. Epinephrine and milrinone infusions were weaned and then discontinued on day+15. On day +17, echocardiogram showed a significantly improved and normal LVSF of 36% and LVEF (biplane) of 64%. On day+18, his weight returned to baseline, and his creatinine and fibrinogen normalized. On day+21, he was
transferred from the intensive care unit to the stem cell transplant unit. His mental status was back to baseline by that time, but he continued with dysarthria for another week before it too returned to baseline.

On day+29, a BMBA and CSF analysis demonstrated MRD-negative remission via flow cytometry (<0.01% of mononuclear cells) and high-throughput sequencing (<1x10⁻⁵) techniques, and his CSF showed no lymphoblasts. He had an absolute CD19 count of 0 cells per microliter in the peripheral blood. At months 3 and 6 post-tisagenlecleucel, BMBA showed MRD-negative remission with ongoing B-cell aplasia. Clinical remission and B-cell aplasia were sustained for 12 months after infusion.

**Discussion**

We describe a patient with a high burden of CD19+ B-ALL treated with tisagenlecleucel who developed life-threatening CRS with features of HLH, including persistent fever, hyperferritinemia (>202,000 ng/ml), cytopenias, splenomegaly, and hypofibrinogenemia, that was initially refractory to tocilizumab, and was treated with corticosteroids, a second dose of tocilizumab, siltuximab, and emapalumab with subsequent clinical improvement. As there were numerous interventions including IL-6 blockade, corticosteroids, and therapeutic cooling surrounding the use of emapalumab, it is not possible to attribute definitive causality to any particular intervention. However, persistent fever, hypotension, and persistently elevated CRP suggested IL-6 blockade was insufficient after two doses of tocilizumab. Furthermore, fever and hypotension persisted and vasopressor requirements increased after siltuximab, despite a decreasing CRP suggesting effective IL-6 blockade. While it is unknown if delayed action of these agents would have led to clinical improvement, the initial refractory nature led to the consideration of additional cytokine blockade using an agent that is indicated in HLH and that
blocks IFN-γ activity, which is known to be hyperactivated in CRS. The timing of emapalumab on day+9 preceded improvements in markers of HLH that had been worsening, as was seen with emapalumab use in primary HLH. Fever, ferritin, and CRP measurably improved within a day of emapalumab, and hypofibrinogenemia, acute heart failure, and renal failure, which are typically late findings in CRS, resolved within the following week. However, on day+8 prior to emapalumab, IL-6 and IL-8 levels were notably elevated, but IFN-γ was normal. It is therefore unclear whether IFN-γ elevation was associated with CRS severity in this case, although correlative data from clinical trials of tisagenlecleucel would suggest IFN-γ substantially increases early in the course of severe CRS. CXCL9, induced by IFN-γ and thought to be a more sensitive measure of tissue IFN-γ, was not available. We hypothesize that CXCL9 would have been a more accurate measure of IFN-γ pathway activity and blockade in this case; however, limited cytokine data and lack of rapid testing options precluded the use of cytokine levels in clinical decision-making.

This case illustrates the challenges of identifying and studying effective therapies for refractory CRS. In the setting of life-threatening CRS refractory to initial cytokine blockade with the now-standard management of tocilizumab, often multiple interventions are utilized in quick succession, making it difficult to tease out individual contributions. Moreover, additional cytokine blockade may be more effective at an earlier timepoint. Real-time cytokine measurements may point to potential targets and optimal timing; however, the limited availability of cytokine assays to provide serial measurements with sufficient rapidity challenge their widespread use in clinical practice. Correlative studies and preclinical modeling can assist in identifying potential targets. As elevated IFN-γ is associated with and predictive of severe CRS and preclinical studies suggest blockade reduces macrophage activation and cytokine
production\textsuperscript{15}, IFN-γ may be a potential target for the treatment of severe CRS. Several other therapies garnered support through preclinical or anecdotal data. Anakinra, an IL-1R antagonist, is currently being studied in clinical trials (NCT04432506, NCT04150913, NCT04148430) for the prevention or treatment of CAR-associated CRS and ICANS based on preclinical evidence for the role of IL-1 in these toxicities\textsuperscript{6,7}. The tyrosine kinase inhibitor dasatinib has been shown to reversibly inhibit cytokine production and CAR T-cell cytotoxicity in preclinical models, suggesting its potential utility in life-threatening CRS\textsuperscript{14}. While prospective clinical trial data are lacking, these therapies warrant further study.

Ideal management of CRS or ICANS would reduce hyperinflammation and end-organ damage without significantly limiting the cytotoxicity or persistence of CAR T cells. As emapalumab neutralizes IFN-γ that CAR T cells and genetically unmodified lymphocytes secrete, there is potential for reduction of CAR T-cell cytotoxicity with IFN-γ blockade. Indeed, IFN-γ signaling has been shown to be indispensable for CAR T-cell killing in solid tumor models\textsuperscript{18}. However, there is preclinical evidence that IFN-γ blockade or genetic knockout may not impair CAR T-cell cytotoxicity against hematologic malignancies\textsuperscript{15}. Our patient’s ongoing remission and B-cell aplasia 12 months after tisagenlecleucel suggests that use of emapalumab in the setting of refractory grade 4 CRS did not meaningfully interfere with the efficacy or persistence of CAR T-cells; however, it is not known whether IFN-γ blockade could interfere with CAR T-cell expansion or function in other situations, particularly if utilized prior to peak expansion.

Prospective clinical trials of IFN-γ blockade are needed to determine the impact on both toxicity and efficacy.

Treatment options for life-threatening CRS and ICANS refractory to first-line treatment with tocilizumab and corticosteroids are needed as there is no well-studied or standard approach.
Suggested alternatives and agents used in the treatment of primary HLH (cyclophosphamide, tyrosine kinase inhibitors, T-cell lytic agents, etoposide) are likely to be toxic to T cells and carry additional toxicity risks. Therefore, targeted cytokine blockade directed at the pathophysiology of HLH and the triggering process is preferable. As the use of T-cell-engaging therapies expands, further study of IFN-γ blockade in human subjects with CRS after CAR T-cell and IEC therapy is warranted.
